  - You'll need cellular data

# Option Valuation

- Why study the valuation of options?
  - Value = Risk
  - Proper valuation of transactions
  - More than vanilla options have “option value”

# Option Examples

---

## Vanilla options

- Call
- Put
- Straddle
- Swaptions

## Physical Options

- Thermal power assets
- Hydro assets
- Transmission
- Gas storage and transport
- Others?

## Why study option valuation?

- To properly value an option position
- To better understand the derivation of risk
- To properly value physical asset positions
- Good times
- All of the above

# Overview and Terminology

---

# Options - Overview

---

- Option: An option is an instrument that gives the holder the right, *but not the obligation*, to buy or sell the underlying at a specific price
- Components of an option:
  - Strike price
  - Underlying price
  - Volatility
  - Time to expiration
  - Interest rate
  - Others

# Options – Payout Functions

---

- Call: The *option* to buy the underlying at a specific price (strike price);

$$\text{Max}(\text{Underlying} - \text{Strike Price}, 0)$$

- Put: The *option* to sell the underlying at a specific price (strike price);

$$\text{Max}(\text{Strike Price} - \text{Underlying}, 0)$$

# Options – Payout Functions

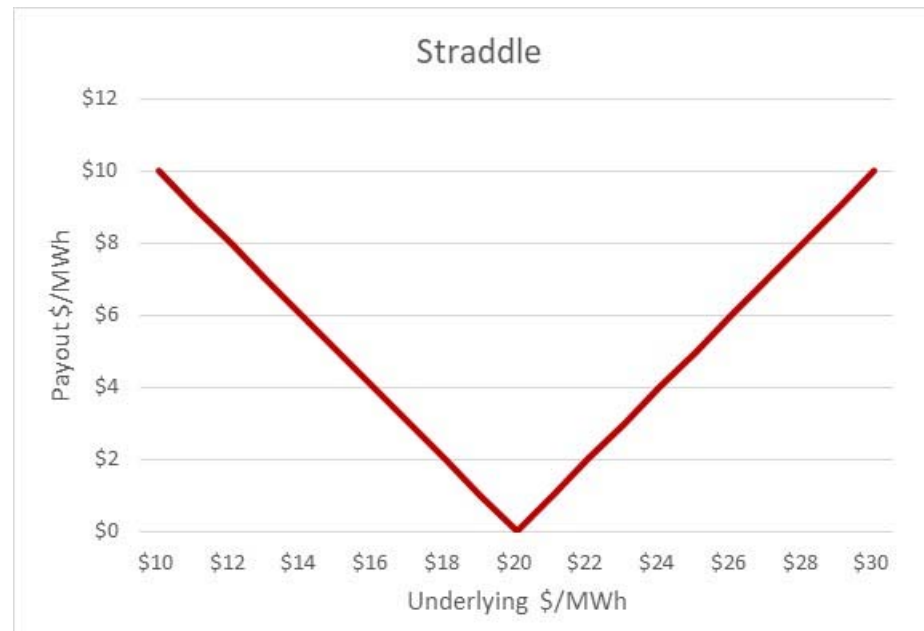

Example: Underlying price = \$26 and  
Strike Price = \$20  
Payout at expiry =  $\text{Max}(\$26 - \$20, 0) = \$6$

Example: Underlying price = \$12 and  
Strike Price = \$20  
Payout at expiry =  $\text{Max}(\$20 - \$12, 0) = \$8$

# Options - Combinations

- Straddle: Simultaneously long/short a call and put with the same strike and expiration
- Why might straddle pricing be useful?

# Options – Spread Options

---

- Other examples of combinations
  - *Cross-commodity spread*: Long an option in one commodity, short an option in another. Examples include spark-spread option or crack-spread option
  - *Locational spread*: Long in one area, short in another. Examples include gas transport and transmission
  - *Calendar spread*: Long in one time period, short in another. Example is gas storage.

# Options - Terminology

---

- *European Option*: Option that can only be struck at the time of expiry
- *American Option*: An option that can be struck anytime *before* time of expiry
- *Volatility*: Standard deviation of the returns of prices
- *Implied Volatility*: Markets assessment of volatility (solve for volatility of a traded option price)
- *Correlation*: Correlation of the returns on two (or more) different underlying instruments

**If you wanted to take a position PJM-W that benefited from a large move in the underlying, regardless of the direction, what would be an appropriate option position?**

Long a call

Long a put

Short a  
straddle

Long a  
straddle

# Modeling

---

# Options – Inputs

---

- What inputs/data do we need?

Option Type:  
Call or Put

Prices: Strike and  
Underlying

Volatility and  
Correlation

Time to Expiration  
(Expiry)

Interest Rate

Others?

# Options – Inputs

## Volatility

- Historical
- Daily or monthly? Or both?
- Market implied volatility
- Is there a “market”

## Correlation

- Historical
- Implied?
- Long lever, *be careful*
- More art than science

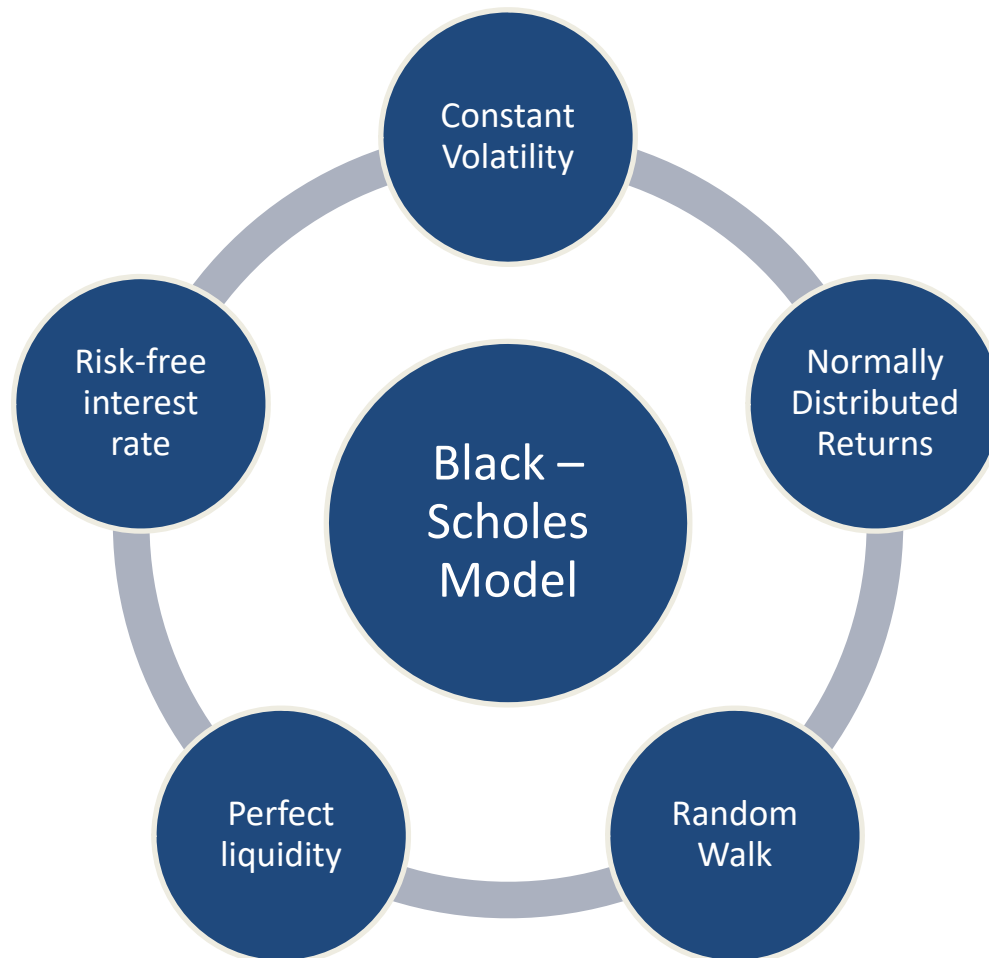

# Options – Modeling

---

- Two primary methods for valuation
  1. Black-Scholes model
    - a) Generally associated with “closed-form” modeling
    - b) Analytical solution, not numerical
    - c) Different form exist, notably for spread-option modeling
  2. Simulation
    - a) Often referred to as “Monte Carlo”
    - b) Generic terminology that has numerous different applications, and more importantly, techniques

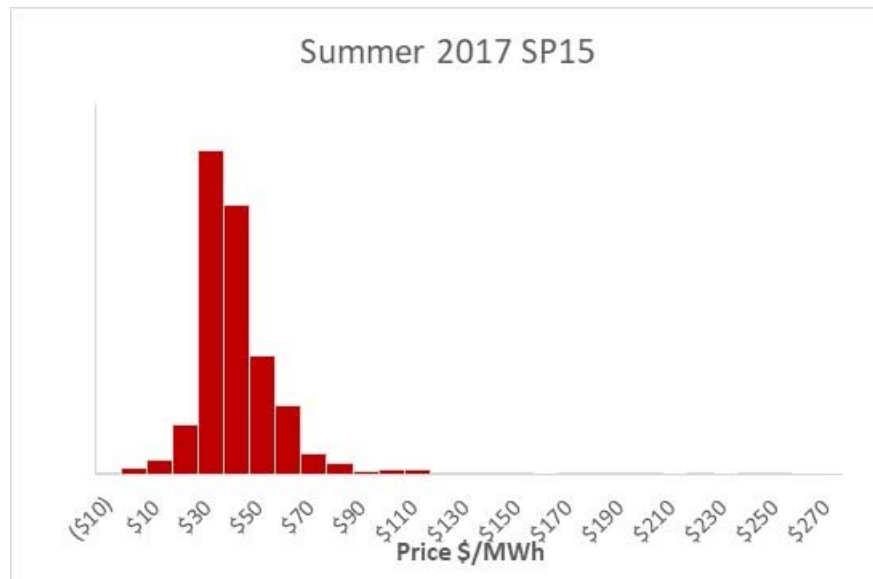

# Black-Scholes Assumptions

---

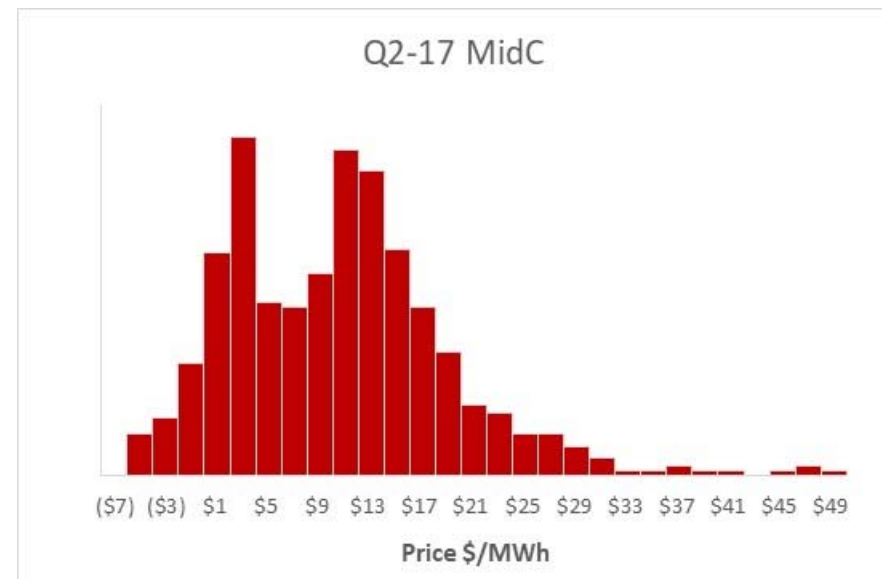

# Black-Scholes Assumptions

Normally Distributed Returns?

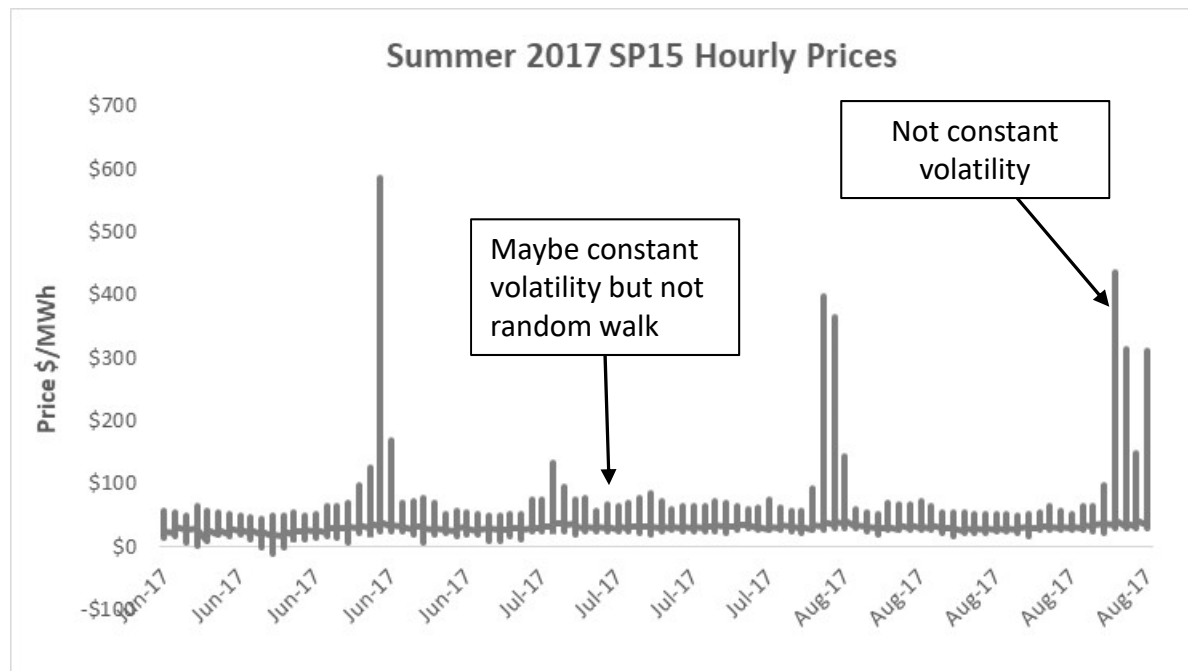

No.

No.

# Black-Scholes - Assumptions

Random Walk? Constant Volatility?

# Black-Scholes Model

---

## Strengths

- It can be a powerful tool, if used properly
- Easy
  - Computationally
  - Implementation
  - Anyone can run it
  - Low cost
  - Integrated into ETRM, booking

## Weaknesses

- Valuations can be grossly inaccurate, if not used properly
  - Inputs need to be carefully calculated
  - Inputs usually need to be massaged, accounting for underlying assumptions
  - The more complex the product, the less realistic the valuation

# Simulation (Monte Carlo) Models

---

- Monte Carlo based models are computational algorithms that model uncertainty using random number generation (sampling)
- There are numerous simulation based techniques for modeling risk, valuing options, and physical assets
- These models allow you to:
  - Capture path dependent nature of commodity prices, i.e. *not random walk*
  - Capture *mean reversion* tendency of commodity prices
  - Random jump or diversions, i.e. *non-constant volatility*
  - More easily model physical idiosyncrasies of commodity assets or highly complex options

# Simulation (Monte Carlo) Models

---

- Simulations can be used to value almost anything, example models include:
  - Mean-reversion models
    - Options with daily strikes
  - Mean-reversion with jump diffusion
    - Options with daily strikes, underlying has random jump/diversions
    - Examples include anything with hourly price paths
  - Multiple price paths with embedded correlations
    - Cross-commodity spread options, e.g. power and gas correlated
    - Full-requirements load transactions, load and price correlated
    - Hydro optimization (with embedded linear optimization techniques), hydro and price correlated

# Simulation (Monte Carlo) Models

---

## Strengths

- Model pretty much anything
- Accounts for many of Black-Scholes shortfalls
- Much easier to account for physical nature of commodity assets
- Works well with optimization techniques

## Weaknesses

- Computationally expensive
- Need the appropriate human capital
- Not easily integrated into ETRM, booking
- Complex, not easily explained

Which model would you use to value a March 2018 NYMEX call option? Assume its at-the-money and monthly strike.

Black-Scholes or  
other closed-form  
model

Monte Carlo  
(simulation based  
model)

Which model would you use to value a calendar 2020 daily heat rate call option? Assume ERCOT North Zone power, HSC gas, 8 heat rate, and all hours.

Black-Scholes  
or other closed  
form model

Monte Carlo  
(simulation  
based model)

# Greeks and Square Root of Time

---

# Option Greeks

- Option Greeks measure an options sensitivity given changes in certain factors.
- Most commonly these include delta, gamma, theta, vega, and rho.

Hint: Not these  
Greeks

# Option Greeks

---

- Delta: The sensitivity in the price of an option given a change in the underlying
- Gamma: The sensitivity in the delta of an option given a change in the underlying
- Theta: Sensitivity to the price of an option given a change in time
- Vega: Sensitivity to the price of an option given a change in volatility
- Rho: Sensitivity to the price of an option given a change in the interest rate

# Option Greeks - Delta

---

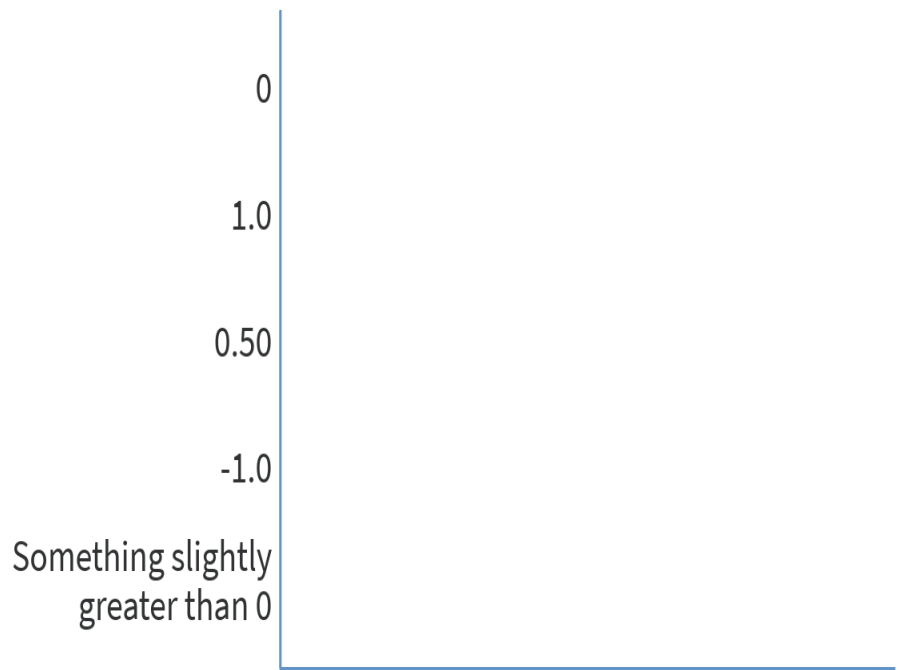

- What can delta be used for?
  - Provides quantity of the underlying you *may* want to hedge to be “risk neutral”
  - Gives you your net position in an underlying, can be netted across multiple positions
- Calculated as a number between 0-1
  - Close, but not quite the probability of the option being in-the-money at expiry

# Option Greeks - Delta

---

- Long call makes you long delta
  - Long an at-the-money call is a  $\sim 0.50$  delta
  - Short an at-the-money call is a  $\sim -0.50$  delta
  
- Long put makes you short delta
  - Long an at-the-money put is a  $\sim -0.50$  delta
  - Short an at-the-money put is a  $\sim 0.50$  delta

## What is the delta of an at-the-money straddle with expiration in January 2019?

# Option Greeks - Gamma

---

- Who cares?
  - Gamma tells you how fast (or not) your position can change
  - Long gamma, one benefits from a move in the underlying
  - Short gamma, one loses on a move in the underlying
  - The higher the gamma, the more option value to be extracted from delta hedging

# Options - Square Root of Time

- Option prices are proportional to the square root of time
- This is a critical consideration when valuing options or assessing risk
- The more time until expiry, the more an option is worth
- Conversely, the longer dated a position the more risk as the more price can move

# Options - Square Root of Time

# Market Valuation

---

**How much would you pay for an at-the-money July 2018 PJM-W  
Monthly Call Option? Underlying is \$39.00/MWh**

# Key Takeaways

---

- Understanding the key assumptions of modeling and distributions of underlying is critical
- There is option value embedded in much more than vanilla options
- Understanding option valuations and assessing risk are one and the same

Thank you!
